### Abstract

Adaptive phenotypic plasticity, the ability of an organism to change its phenotype to match local environments, is increasingly recognized for its contribution to evolution. However, few empirical studies have explored the molecular basis of plastic traits. The East African cichlid fish Astatoreochromis alluaudi displays adaptive phenotypic plasticity in its pharyngeal jaw apparatus, a structure that is widely seen as an evolutionary key innovation that has contributed to the remarkable diversity of cichlid fishes. It has previously been shown that in response to different diets, the pharyngeal jaws change their size, shape and dentition: hard diets induce an adaptive robust molariform tooth phenotype with short jaws and strong internal bone structures, while soft diets induce a gracile papilliform tooth phenotype with elongated jaws and slender internal bone structures. To gain insight into the molecular underpinnings of these adaptations and enable future investigations of the role that phenotypic plasticity plays during the formation of adaptive radiations, the transcriptomes of the two divergent jaw phenotypes were examined. Our study identified a total of 187 genes whose expression differs in response to hard and soft diets, including immediate early genes, extracellular matrix genes and inflammatory factors. Transcriptome results are interpreted in light of expression of candidate genes-markers for tooth size and shape, bone cells and mechanically sensitive pathways. This study opens up new avenues of research at new levels of biological organization into the roles of phenotypic plasticity during speciation and radiation of cichlid fishes.

### Introduction

Recent years have seen a renewed interest in hypotheses that were originally put forward by Waddington and Schmalhausen, namely that phenotypes are not determined solely by the genotype, but rather through interactions between the genotype and internal and external environmental influences (Schmalhausen 1949; Waddington 1953; Gilbert 2001, 2012; Bosch & McFall-Ngai

Correspondence: Axel Meyer, Fax: +49 (0) 7531 88 3018; E-mail: axel.meyer@uni-konstanz.de 2011). Through providing a better match to local environments than purely genetically encoded phenotypes, environmentally induced phenotypes can offer a selective advantage, providing fuel for evolution (West-Eberhard 2003, 2005; Pigliucci 2007; Jablonka & Raz 2009). Developmental plasticity is known to be the basis of divergent adult phenotypes in well-known adaptive radiations such as spadefoot toads (Gomez-Mestre & Buchholz 2006), sticklebacks (Day *et al.* 1994; Day & McPhail 1996; Wund *et al.* 2008) and *Anolis* lizards (Losos *et al.* 2000; Kolbe & Losos 2005), potentially contributing to their speciation. Even phenotypic

plasticity itself is a trait that appears to be subject to natural selection (Crispo 2007; Schwander & Leimar 2011). Divergent traits that arise initially through phenotypic plasticity can subsequently be encoded by the genome through the process of genetic assimilation and enriched through natural selection (Schmalhausen 1949; Waddington 1953; West-Eberhard 2003; Schwander & Leimar 2011). Current neo-Darwinian paradigms do not account for the role of phenotypic plasticity in speciation, maintaining an exclusive focus on heritable variability (Pigliucci 2007). However, as natural selection acts upon phenotypes rather than on genotypes, determining whether genetic assimilation contributes to speciation remains an important unanswered question of evolutionary biology—one that potentially allows us to bridge genotypic and phenotypic aspects of evolution. It has now become possible to address an important aspect of phenotypic plasticity that remained largely unknown until now: its molecular basis (Aubin-Horth & Renn 2009; Beldade et al. 2011). The understanding of this is also the key to testing the importance of genetic assimilation, as regulatory evolution of plasticity-related genes has the potential to mediate their environmental responsiveness and thus, the degree of phenotypic plasticity displayed by different lineages.

Cichlid fishes of the East African rift lakes have formed famously diverse adaptive radiations that arose by extremely rapid speciation. They display an astonishing array of morphological and behavioural traits in spite of their young evolutionary age-in the case of Lake Victoria, its 500 species are <100 000 years old-and are characterized by only minute genetic differences (Meyer et al. 1990; Salzburger et al. 2005; Kishe-Machumu et al. 2008; Elmer et al. 2009). Phenotypic plasticity may have contributed to cichlid diversification as it is known to generate morphological variants that responded to altered feeding ecologies, facilitating access to new trophic niches or to a more efficient exploitation (Meyer 1987, 1993; Wimberger 1994; Stauffer & Gray 2004). To date, the best-studied cichlid example of phenotypic plasticity involves hypertrophy of the lower pharyngeal jaw (LPJ) of Astatoreochromis alluaudi in response to a mechanically robust diet, making it an excellent model system in which to characterize the molecular basis of phenotypic plasticity (Fig. 1a) (Greenwood 1959, 1965; Hoogerhoud 1986b; Huysseune et al. 1994; Huysseune 1995; Smits et al. 1996b).

Cichlids posses a pharyngeal jaw apparatus (PJA) with unique morphological features that facilitate the exploitation of a myriad of trophic niches including the crushing of very hard food items such as particular lineages of snails (Fig. 1b). Comprised of the upper and lower pharyngeal jaws and associated muscle attachments, the cichlid PJA represents a second functional

set of jaws that take over the role of mastication from the oral jaws. This has lead to a functional decoupling between the oral and pharyngeal jaws, expanding their 'degrees of freedom' to evolve considerably more diverse modes of food acquisition than virtually all other families of fishes (Liem 1973). As a result, the cichlid PJA has been interpreted as an evolutionary key innovation that may, at least in part, be responsible for the extraordinary evolutionary success of cichlids (Liem 1973; Stiassny & Jensen 1987).

Astatoreochromis alluaudi is a relatively widely distributed cichlid species, inhabiting Lake Victoria, as well as its surrounding satellite lakes (Greenwood 1959, 1965). Two morphs have been identified for this species: a molariform morph with a robust LPJ (Liem 1973; Stiassny & Jensen 1987), studded with large, molar-like teeth; and a papilliform morph with a more gracile LPJ, bearing small, delicate teeth (Hoogerhoud 1986b; Huysseune et al. 1994; Huysseune 1995). Molariform populations inhabit Lake Victoria, feeding primarily on hard-shelled snails, which are cracked using their robust pharyngeal jaws (Greenwood 1965; Witte 1981), while individuals from satellite lake populations are more often papilliform, ingesting a range of softer food items, with a preference for insects (Slootweg et al. 1994). Molariform and papilliform jaws show a higher degree of efficiency in processing hard and soft diets, respectively (Meyer 1989); thus, each phenotype represents a trade-off and is adaptive depending on the ecological niche in which it is expressed. So striking are the differences in LPJ morphology that these populations were initially classified into two separate subspecies (Greenwood 1959). Later, it was recognized that these differences are caused by phenotypic plasticitywhen Greenwood examined an adult aquarium-bred individual, descended from a wild-caught Lake Victoria (molariform) stock, he found that its LPJ differed markedly from the source population, more strongly resembling satellite lake (papilliform) specimens (Greenwood 1965). Several further studies have shown that for A. alluaudi as well as other species of cichlid fish, the LPJ morphology is affected by diet, where a hard diet induces a molariform LPJ and a soft diet retains an ontogenetically and phylogenetically earlier papilliform LPJ (Greenwood 1965; Hoogerhoud 1986b; Smits 1996; Muschick et al. 2011). Detailed morphological analyses of A. alluaudi's LPJ suggest that mechanical strain induced by cracking hard-shelled snails is instrumental in shaping the molariform morphology (Huysseune et al. 1994; Huysseune 1995); however, to date, this phenotypic response had not been examined at the molecular level.

Mechanical forces are inherently linked to skeletal development, whereby the shape, size and density of bones typically reflect the forces applied to them—an

**Fig. 1** (a) *Astatoreochromis alluaudi*, an East African cichlid includes two naturally occurring morphs that differ in their trophic ecologies and morphology of their pharyngeal jaws. Photograph provided by Erwin Schraml. (b) The pharyngeal jaw apparatus of cichlid fishes displays three morphological features that make it well suited to crushing: (i) the upper jaw articulates with the neurocranium, (ii) the lower pharyngeal jaw (LPJ) is suspended in a muscular sling, connecting the neurocranium to the posterior muscular arms of the lower jaw and (iii) the two 5th gill arches are sutured to form a single unit, the LPJ. (cl) Cleithrum, (h) hyoid, (lpj) lower pharyngeal jaw, (nc) neurocranium, (oj) oral jaw, (upj) upper pharyngeal jaw are indicated. Image modified from (Mabuchi *et al.* 2007).

idea originally described by Julius Wolff (Chamay & Tschantz 1972). Since then, considerable insight has been gained on the cellular and molecular basis of bone growth and modification, through both in vitro and in vivo investigations on mammalian bones (Liedert et al. 2006; Thompson et al. 2012). Lacking osteocytes (living cells embedded in bones), which are assumed to be units of strain detection, the acellular bones of derived teleosts (such as cichlids) display fundamental differences to those of mammalian cellular bones (Moss 1962). Modelling and remodelling in derived teleosts largely relies on mononucleated osteoclasts (boneresorbing cells), which differ considerably from the massive multinucleated osteoclasts of mammals. Still, common pathways regulate osteoclasts both in teleosts and mammals (Witten & Huysseune 2009). In mammals, bone remodelling is achieved through the tightly coupled activity of osteoclasts and osteoblasts (bonesecreting cells) (Lemaire et al. 2004). This response is coordinated by osteocytes, which sense localized shear stresses in the bone, launching a transcriptional response that leads to the proliferation and differentiation of both osteoblasts and osteoclasts (Klein-Nulend et al. 2005; Bonewald 2011). Previous investigations on mammalian bone provide sets of candidate genes of known function that can be investigated comparatively in fish.

In this study, the molecular basis of diet-induced plasticity in *A. alluaudi*'s LPJ was examined through using combined morphological and transcriptional investigations. Several pathways underlying the molariform phenotype were identified, many of which are known to respond to mechanical strain in the bones and teeth of mammals. Furthermore, we identified the upregulation of several genes that promote osteoblast proliferation and differentiation, matrix remodelling and calcium signalling, and the downregulation of

inflammatory markers, which together are likely to shape the molariform morphology. Our study sheds light on questions concerning the molecular basis of phenotypic plasticity, opening the door for future studies of genetic assimilation that investigate its potential contribution to the adaptive radiation of cichlid fishes. Moreover, we add to previous molecular studies of phenotypic plasticity in cichlids (Burmeister *et al.* 2005; Aubin-Horth *et al.* 2007; Renn *et al.* 2008; Huffman *et al.* 2012).

### Material and methods

### Specimens used in this study

We conducted a controlled diet experiment on an inbred strain of Astatoreochromis alluaudi, obtained from Frans Witte in 2008, which was originally collected from the Mwanza Gulf of Lake Victoria in 1984. A single brood, ~60 individuals, was raised on Artemia salina nauplii and TetraMin flake food until they reached 30 mm standard length (SL). This brood was then divided into two groups in substrate-free 100-L aquaria for 18 months on one of two experimental diets: the hard diet (HD) group was fed hard-shelled gastropod molluscs (Melanoides sp.), and the soft diet (SD) group was fed equivalent amounts of frozen, pulverized Melanoides sp. snails (similar to methods described in Muschick et al. (2011)). The diets were supplemented with TetraMin flakes. At the end of the experimental period, fish were sexually mature and many exceeded 80 mm SL, a size at which overt differences in jaw morphology were expected (Hoogerhoud 1986a; Huysseune et al. 1994; Smits et al. 1996b). Fish were killed according to local ethics regulations, and LPJs were dissected up to 30 min after feeding, so as to capture the patterns of transcription induced by a robust diet on both immediate and long-term levels. LPJs were stored in RNAlater (Qiagen) according to manufacturer's instructions for subsequent use in morphometric and transcriptional analyses.

### Morphometric analyses

While submerged in RNAlater, LPJs were cleaned of surrounding connective tissues and photographed in both dorsal and ventral orientations under a dissection microscope. LPJs were then weighed to an accuracy of 0.0001 g after RNAlater was blotted with a Kimwipe. To test for differences in size between treatments and to facilitate comparison to previous studies, linear measurements were obtained either digitally from photographed specimens, or with dial callipers in the case of jaw depth (Fig. 2a-d). The area and centroid size of each pharyngeal jaw were estimated from the x y coordinates of landmarks and semilandmarks that were also used in the geometric morphometric analysis (Fig. 2d; see below) by using Matlab (version R2010a; Mathworks Inc.). Additionally, pharyngeal jaw volume was estimated by multiplying LPJ area by LPJ depth. Tooth size was estimated by adding together measurements of

Fig. 2 Measurements made for traditional and geometric morphometric analyses. Traditional morphometric measurements included (a) central toothed area (cta), dentigerous length (den len), (b) length (len), width (w), left horn width (lhw), right horn width (rhw), suture width (sut wid) and (c) depth (d). (f) Landmarks and semilandmarks used for the geometric morphometric analyses, and for calculation of area.

tooth length and width, which were obtained from the photographs. Each of these measurements was then log-transformed and subjected to an analysis of covariance (ANCOVA) in STATISTICA (StatSoft, Inc.), using SL as a covariate (to account for allometric variation) and sex and treatment as categorical variables. A principal component analysis (PCA) was also carried out in NTSYSpc (Rohlf 2007a) on the correlation matrix of the log-transformed measurements, producing plots of the scores on the first two PC axes to explore overall patterns of variation in the data set.

Using digital images of ventrally oriented LPJs, 16 points (Fig. 2d), including landmarks (points 1 and 9) and semilandmarks (the remaining points), were digitized with IMAGEJ (Schneider et al. 2012). The configurations of points were then subjected to a Generalized Procrustes analysis with sliding of semilandmarks (Bookstein 1997) using the software tpsRelw (Rohlf 2007b). As pharyngeal jaws are symmetrical structures, analyses were performed only on the symmetric component of shape variation (Klingenberg et al. 2002). A multivariate regression of shape variables on body SL was carried out to account for allometric variation in shape, and residuals were used in subsequent analyses. Treatments were compared using discriminant analysis in MorphoJ (Klingenberg 2011), testing the significance of between-treatment differences in mean shape using a permutational procedure based on Procrustes distances (1000 permutations). The accuracy of classification of the discriminant function was estimated with the leaveone-out cross-validation implemented in the software.

### RNA extraction

RNA was extracted from LPJs using a method modified for bone tissue, which combines Trizol (Invitrogen) with RNeasy (Qiagen) extraction, similar to (Mantila Roosa *et al.* 2011b). Modifications included an additional homogenization step using a FastPrep-24 (MP Biomedicals), prior to phase separation, and an on-column DNase treatment, which was conducted according to manufacturer's instructions (Qiagen). RNA purity and integrity were assessed by spectrophotometry (Eppendorf) and Bioanalyzer 2100 (Agilent) (Table S1, Supporting Information).

### Candidate gene qRT-PCR

Sixteen candidate genes were selected for qRT-PCR analysis (Table 1). These include genes that are known to establish tooth size and patterning [*pitx2, eda, shh, bmp2, bmp4,* described in (Fraser *et al.* 2008, 2009)], genes that respond to mechanical strain in mammalian bones [*bmp2* and *bmp4* (Sato *et al.* 1999), *pghs2*

(Klein-Nulend et al. 1997), nos (Rubin et al. 2003), cx43 (Su et al. 1997), wnt5a (Hadjiargyrou et al. 2002) and  $\beta$ -catenin (Robinson et al. 2006)], representatives of the osteoblast proliferation/differentiation pathway (runx2a/ 2b (Ducy et al. 1997; Komori et al. 1997), osx (Nakashima et al. 2002), ap (Owen et al. 1990) and bmp2 (Tsuji et al. 2006)) and the osteoclast pathway (opg (Udagawa et al. 2000) and RANK-L (Schoppet et al. 2002)). It was hypothesized that each of these genes may be upregulated in response to the HD treatment (Table 1), thus contributing to the molariform morphology, representing a departure from the baseline condition of this species. Specifically, the upregulation of: mechanical strain response genes would occur in response to snail cracking, the upregulation of osteoblast proliferation/differentiation genes and osteoblast pathway genes together would explain the alterations in size and shape, and tooth-patterning genes would be required for the development of enlarged tooth germs.

Eight of these genes were cloned using degenerate primers (*pghs2, nos, wnt5a, \beta-catenin runx2a/2b, osx, ap, opg* and *RANK-L*; Table S2, Supporting Information), and the remaining eight were obtained from transcriptome reads generated by our RNA-seq experiment (see below). Orthology was confirmed through construction

of maximum-likelihood trees using Jalview (Waterhouse *et al.* 2009) and PhyML (Guindon *et al.* 2010) (Fig. S1, Supporting Information).

Primer pairs were designed so that the reverse primer was situated in the 3' UTR of each gene (Table S2, Supporting Information). Primer concentration was optimized so that negligible dimers were produced in the negative control (>10 cycles after the positive control). RNA was verified to be free from gDNA contamination through noRT control reactions. cDNA was synthesized from 1.0 µg of each RNA using Superscript III (Invitrogen), primed with oligodT and diluted 1:10 for use in qRT-PCR reactions. Reactions were run on 22 cDNA samples (12 HD and 10 SD) using a cfx96 Real Time System (Bio-Rad) with the SYBR green iQ supermix (Bio-Rad), using the following conditions: 95 °C 3 min, then 40 cycles of 95 °C 10 s, 55-60 °C 30 s, 72 °C 30 s. Efficiency was calculated through the generation of a standard curve, based on serial dilutions of pooled cDNAs (1:5, 1:10, 1:20, 1:40, 1:80). Housekeeping genes were selected from the RNA-seq results (see below), searching for genes with the lowest between-sample variability. The housekeeping genes were tested using gBase (Hellemans et al. 2007), and two genes, actinR and twinfilin were shown to display sufficiently low variability to enable the calculation of a reliable normalization factor (NF). Relative quantitation was calculated for each sample using the algorithm described in (Simon 2003), which were scaled against NF. Comparisons of the levels of gene expression between treatments were then performed using the bootstrap version of the t-test implemented in SPSS (IBM Corp.).

### RNA-seq

We performed RNA-seq in an effort to identify novel regulators of plasticity in the Astatoreochromis alluaudi LPJ. Ten individually barcoded cDNA libraries were synthesized (Table S1, Supporting Information) using the Illumina TruSeq RNA sample preparation kit according to manufacturer's instructions (Illumina, San Diego, CA, USA). The barcoding enabled multiplexing, eliminating potential biases created by lane-to-lane variability (Auer & Doerge 2010). Paired-end sequencing (72 bp from each end) of clustered template cDNA was performed using an Illumina Genome Analyzer IIx (Illumina). The resulting reads were then trimmed with CLC Genomic Workbench (version 4.9; CLC bio, Aarhus, Denmark), and de novo assembled using VELVET (version 1.2.01) (Zerbino & Birney 2008) and OASES (version 0.2.05) (Schulz et al. 2012) with Kmer lengths ranging from 29 to 49. Annotation was performed through blastx comparison to the Medaka genome, a model system that is closely related to cichlids, in the Ensembl database (Hubbard et al. 2002). We mapped the filtered reads to the assembled transcripts using BOWTIE (version 0.12.9) (Langmead et al. 2009) and extracted the digital expression value for each sample using EXPRESS (version 1.3.0) (Roberts & Pachter 2012). Differentially expressed (DE) genes were identified through comparisons between the LPJ samples of 5 HD (molariform) and 5 SD (papilliform) individuals (Table S1, Supporting Information), using edgeR (version 3.0.8) (Robinson et al. 2010) and DESeq (Anders & Huber 2010), with correction of false discovery rate 0.1. Both edgeR and DESeq (version 1.10.1) are based on a negative binomial model, but they also differ in a few steps [for example, see Dillies et al. (2012)]. Only the genes that were identified by both edgeR and DESeq (a total of 183) were included in further analyses-this conservative approach has been endorsed by recent research as a means of controlling the inclusion of false positives in RNA-seq results (Yendrek et al. 2012). K-means clustering of the DE genes was performed based on a K-means calculation script (define clusters by cutting tree.pl) on the Trinity website (Grabherr et al. 2011).

To perform the functional annotation of the DE genes, we first converted the Medaka annotations to Human Ensembl gene ID (Release 70). Results were further characterized using the online functional classification tool, DAVID (version 6.7) (Huang *et al.* 2008). Gene functional classification and functional annotation clustering were both performed. Two separate gene lists were generated for functional annotation clustering, comprised of genes that were, on average, up- or downregulated in HD relative to SD. Reported results include clusters with significant EASE scores (>1.0) and annotation terms with *P*-values above 0.1 after performing Benjamini–Hochberg multiple testing correction (Benjamini & Hochberg 1995).

### Results

## Diet influences size and shape of LPJ and teeth in Astatoreochromis alluaudi

After exposing *Astatoreochromis alluaudi* to the hard and soft diets for a period of 18 months, LPJs were dissected and linear and geometric morphometric measurements were made. The two diet treatments, which included intact and pulverized snails, resulted in marked differences in the size and shape of the LPJs and size of the teeth, (Fig. 3a–c; Table S3, Supporting Information), similar to other previous publications (Hoogerhoud 1986b; Huysseune *et al.* 1994; Huysseune 1995; Smits 1996). Taking into account allometric and sex-related variation, all measurements except one, largest tooth size, differed significantly between diethardness treatments (Table S3, Supporting Information). The first two principal components accounted cumula-

**Fig. 3** Diet treatment induces plastic phenotypes in the LPJ of *Astatoreochromis alluaudi*. (a) Correlation of the original variables with the first two PC axes. (b) Scatterplot of the individual observation scores along the first two PC axes. (c) Geometric morphometric analysis indicates a significant difference (P < 0.001) in shape between diet treatments; predicted shape for the hard diet treatment in red, predicted shape for the soft diet in blue.

tively for 88.77% of variance. All included measurements except LPJ depth are highly and positively correlated with the first PC axis (Fig. 3a). The plot of the individual scores along the first two principal components shows a clear clustering of the two diet treatments (Fig. 3b). Geometric morphometric analyses of the LPJs indicate significant shape differences as a result of the diet treatment (P < 0.001) with an 87.5% cross-validated correct classification rate. Specifically, the LPJs of the HD fish display a pronounced enlargement of the medial–posterior edge and a relative reduction in keel length in comparison with SD fish (Fig. 3c), a classic hallmark of molariformity, also observed in noncichlid LPJs (Fruciano *et al.* 2011). These are known adaptations for feeding on hard diets and did not develop in response to the soft diet treatment.

# Mechanically stimulating diet induces altered candidate gene expression

Candidate gene expression was conducted using qRT-PCR on the RNA extracted from the LPJs of hard diet (HD) and soft diet (SD) fish (Tables S1 and S2, Supporting Information). All genes that displayed significant differential expression were upregulated in HD jaws, confirming our hypothesis; however, contrary to our predictions, most genes did not differ in their expression between HD and SD jaws (Fig. 4a, Table S4, Supporting Information). Significant expression differences were detected for some representatives of the osteoblast proliferation and differentiation pathways (bmp2, runx2b, osx; Fig. 4a, Table S4, Supporting Information) (Rickard et al. 1994; Ducy et al. 1997; Nakashima et al. 2002; Nakashima & de Crombrugghe 2003), but not others (runx2a, ap). We also detected significant differential expression of some genes stimulated by mechanical strain in bone (cx43, bmp2) (Ziambaras et al. 1998; Sato et al. 1999), but not others (pghs2, nnos, wnt5a,  $\beta$ -catenin; Fig. 4b, Table S4, Supporting Information). The difference in the expression of only one marker of tooth size and shape was found to be significantly differential (bmp2), whereas the others were not (pitx2, eda, shh, bmp4), and neither were the osteoclast pathway markers (rank-l, opg; Fig. 4c, Table S4, Supporting Information). However, as the LPJ contains many tissue types that are each represented in the homogenized samples of the entire LPJ, we cannot rule out the possibility that these genes (or their protein products) play an important role in shaping the LPJ phenotypes that was not detected by our study.

# Genome-wide transcriptional response to mechanical strain in the LPJ

A genome-wide transcriptome analysis (RNA-seq) was utilized to identify potentially novel transcriptional differences between HD and SD individuals that were not

**Fig. 4** Candidate gene expression analysis of LPJs from *Astatoreochromis alluaudi* fed hard and soft diets. Candidates include markers for (a) osteoclasts and osteoblasts (b) mechanical strain response and (c) tooth number and size. Note that some of the genes in this list have pleiotropic functions, such as *bmp2* and *bmp4*, which also respond to mechanical strain. Blue bars denote means of relative expression in LPJs of soft diet individuals and red bars denote relative expression in hard diet LPJs. SD mean is scaled to 1 and standard error indicated. Asterisks indicate statistical significance according to bootstrap *t*-test (for further details see Table S4, Suppoting Information).

included in the candidate gene-based qRT-PCR approach. This technique uses next-generation sequencing to generate shotgun sequences of cDNA libraries (reads), which, through *de novo* assembly of transcripts, enables the relative quantification of transcript abundance (Wang *et al.* 2009). Differential expression (DE) was analysed using edgeR (Robinson *et al.* 2010) and DESeq (Anders & Huber 2010), yielding a total of 183 genes (Table S5, Supporting Information), which were the subjects of further analyses. A total of 16 698 transcripts were detected amongst our samples. Although some transcripts were undetected for a few samples, each was identified in at least a few individuals of both HD and SD treatments. The significant DE genes did not include any of the original candidates, most likely due to their low mean HD/SD ratios—maximally 1.315 (Table S4, Supporting Information), while the lowest mean HD/SD ratio shown amongst DE RNA-seq genes was 1.496 (Table S5, Supporting Information).

K-means clustering (k = 5) identified two main blocks of genes that were either up- or downregulated in HD vs. SD individuals, in addition to three further clusters with expression that does not adhere strictly to the diet groups (Fig. 5a). Nonetheless, each of the five replicate individuals from the HD and SD groups clustered together, indicating that a mechanically stimulating diet induces a characteristic expression pattern in the LPJ. The three variable clusters contained between 1 and 4 transcripts, each with rather different expression profiles. Thus, we chose to focus on genes up- and downregulated in the HD and SD treatments. The HD treatment stimulated the upregulation of 137 genes, whereas only 46 displayed significantly higher expression in the SD treatment. A rich array of gene classes was induced in the HD LPJs, including muscle-related proteins, various signalling pathways, extracellular matrix and cytoskeleton-related genes (Fig. 5b; Tables S6 and S7 Supporting Information). However, upregulated genes in the SD treatment predominantly included genes most likely involved in the inflammatory response, such as cytokines and chemokines (Fig. 5b; Tables S6 and S8 Supporting Information). As the SD treatment mimics the ground state of this species, it is inferred that expression of these inflammation-related

Fig. 5 Transcriptome characterization of response to mechanical strain in the LPJ of *Astatoreochromis alluaudi*. (a) Heatmap of genes displaying significantly differential expression between HD and SD treatments, as identified by both edgeR and DESeq. (b) Results of gene functional classification clustering generated with DAVID. Category labels represent the top classifying term for each significant gene group identified. Colour coding represents average fold change of genes in each cluster, upregulated in HD = red, upregulated in SD = blue.

### 4524 H. M. GUNTER ET AL.

### Table 2 Gene families identified by RNA-seq, also altered by mechanical strain in mammalian bones

genes is suppressed in HD, rather than being induced in SD.

Notably, our analysis indicated that a substantial number of genes or related gene family members induced in *A. alluaudi* in response to mechanical strain are also observed in studies on mechanical strain in mammalian bones [(Mantila Roosa *et al.* 2011a,*b*; Xing *et al.* 2005), Table 2]. This demonstrates an astonishing degree of evolutionary and apparently functional conservation of molecular bone remodelling mechanisms between mammals and teleosts.

### Discussion

There is mounting evidence that phenotypic plasticity generates adaptive phenotypic variation; however, the underlying genetic and developmental mechanisms for phenotypic plasticity remain largely unknown (West-Eberhard 2003, 2005; Aubin-Horth & Renn 2009; Jablonka & Raz 2009; Beldade et al. 2011). Emerging techniques such as RNA-seq, when used in combination with classical split brood and common garden experiments, can shed light on the molecular basis of phenotypic plasticity in natural populations opening the door to empirically test long-standing controversial theories such as genetic assimilation. The lower pharyngeal jaw (LPJ) of Astatoreochromis alluaudi represents a classical model for phenotypic plasticity, with research dating back almost 50 years (Greenwood 1965; Hoogerhoud 1986a,b; Huysseune et al. 1994; Huysseune 1995; Smits et al. 1996a,b). Our study represents the first molecular investigation of skeletal plasticity in a cichlid fish, determining the transcriptional basis of phenotypic plasticity in the LPJ, a key evolutionary innovation of cichlids.

Amongst the 187 genes that displayed significant differential expression in response to hard diet (including 183 from RNA-seq and 4 from qRT-PCR) are many genes that respond to mechanical strain in the bones of mammals. Thus, our results support the hypothesis that the mechanical strain received from cracking hardshelled snails shapes the molariform morphology (Table 2). Mechanical strain in the bones of mammals induces a suite of biochemical pathways, via localized alterations to fluid flow and subsequent deformation of cellular membranes, which subsequently induce a dramatic transcriptional response (Thompson et al. 2012). Briefly after exposure to even a single loading, mechanical strain induces the expression of immediate early response genes such as *c-fos* and *ier2*, also detected by RNA-seq in our study (Ott et al. 2009; Mantila Roosa et al. 2011b). Relevant candidate genes that were upregulated in HD LPJs include the gap junction gene cx43, which is important in coordinating the cellular response to mechanical strain in mammalian bones (Taylor et al. 2007). Additionally, regulators of osteoblast differentiation and proliferation such as bmp2 (Tsuji et al. 2006) runx2 (Ducy et al. 1997) and periostin (detected by RNAseq) (Nakazawa et al. 2004) are also induced by strain and fractures in mammals.

The functional classes of genes upregulated in HD LPJs provide a potential link between mechanical strain sensing to increased bone density, which was demonstrated for molariform A. alluaudi by previous morphological analyses (Huysseune et al. 1994). In addition to the increased expression of markers for osteoblast proliferation and differentiation (see above), we observed the over-representation of the Gene Ontology terms: extracellular matrix (ECM), intracellular calcium flux, cytoskeleton and muscle (Table 2). Mechanical strain deforms cellular membranes, inducing a characteristic signalling cascade involving calcium influx, alterations to cytoskeletal dynamics and induction of various small GTPases (Chiquet et al. 2009). This secondarily alters the expression of ECM proteins, which influence the structural properties of the ECM to resist the mechanical strain. Collagen VI and collagen XII, amongst the

ECM genes induced in HD fish, both play critical roles in bone development and remodelling through establishing appropriate bone density and matrix organization, respectively (Izu et al. 2011; Christensen et al. 2012). Moreover, the altered expression of various ECM and cytoskeletal proteins in HD fish may influence differentiation of mesenchymal stem cells, as matrix stiffness and cell shape have a profound influence on their differentiation (McBeath et al. 2004; Engler et al. 2006). Interestingly, HD fish overexpressed mef2C, which has been identified as a QTL for bone density in humans (Rivadeneira et al. 2009). Muscle-related genes were also strongly induced in HD fish, an observation, which is consistent with mammalian transcriptome analyses (Mantila Roosa et al. 2011b), perhaps reflecting the extensive cross-talk between pathways expressed in bone and muscle cells (Jähn et al. 2011). Note, care was taken to dissect muscles away from our LPJ samples, increasing the likelihood that this observation reflects altered expression in bone rather than muscle cells.

Several of the identified genes may have pleiotropic functions in generating the molariform phenotype as they are known to function in both bone and tooth development. The teeth of teleosts are replaced continually throughout their lifetimes (estimated to be once per month in A. alluaudi (Huysseune 1995)), and it has been shown that *runx2* and *bmp2* play a role in cichlid tooth replacement (Fraser et al. 2013), representing a redeployment of embryonic tooth developmental pathways (Fraser et al. 2009). cx43 may also play a role in tooth replacement as it is also involved in embryonic tooth development (About et al. 2002). Also the eruption of teeth from adult jaws requires localized bone resorption by osteoclasts, which is orchestrated by c-fos (Wang et al. 1992). Moreover, cx43 and c-fos are upregulated in response to tooth injury (Mitsiadis & Rahiotis 2004), which may plausibly occur in the HD fish as a result of chewing hard-shelled snails. Although further spatial gene expression analyses are required to tease apart the precise function of these genes, this observation opens up the exciting possibility that a pleiotropic network of genes functions in concert to pattern both bones and teeth, seemingly separate, but surely functionally linked, aspects of the overall molariform phenotype.

In HD fish, we also observed striking downregulation of inflammatory response genes including chemokines, cytokines and MHC components, suggesting that the hard diet had an anti-inflammatory effect, which may also be linked to increased bone density. Localized inflammation is linked to increased bone resorption in rheumatoid arthritis (Goldring 2003), via activation of osteoclasts. As osteoclasts are derived from the same hematopoietic stem cell lineage as macrophages and are themselves induced by the cytokine RANK-L (Boyle *et al.*  2003), there is an inherent link between inflammation and bone turnover. cxcr5, one of the chemokines identified by our study, is known to function in bone remodelling through altering differentiation of hematopoietic stem cells (Manolagas & Jilka 1995; Calvi et al. 2003; Tonnarelli et al. 2009). As pharmacological suppression of the inflammatory response is linked to increased bone density (Morton et al. 1998), and chronic exercise is linked to both increased bone density and reduced inflammation (Bruunsgaard 2005), we predict that through suppressing background levels of inflammation, HD fish achieve enhanced bone deposition, potentially though reducing the activity of osteoclasts. Further histological analyses are required to determine whether HD fish do display subphysiological levels of inflammatory cells, and whether this is concomitant with a reduced abundance of osteoclasts. Future research should also determine whether the reduced expression of inflammatory factors is localized to the LPJ, or whether it reflects immunosuppression of HD individuals, presenting a potential cost of plasticity, which may be extremely relevant amongst natural populations.

As they link strain sensing to altered cellular recruitment, the genes identified by this study provide a toolkit for determining the degree to which phenotypic plasticity shapes LPJ morphology in natural populations of A. alluaudi, and whether plasticity is playing a role in their evolution. Ecological conditions that remain stable between generations would be expected to favour the fixation of either molariform or papilliform jaw morphologies, with this trait ultimately losing its environmental sensitivity (genetic assimilation) (Waddington 1953; Crispo 2007). Indeed, A. alluaudi from Lake Saka display molariform LPJs even though hard-shelled snails only comprise a small proportion of their diet (Cosandey-Godin et al. 2008). Moreover, populations that inhabit hypoxic environments display papilliform jaws, which accommodate increased gill size, in spite of the potential to eat snails in these habitats (Binning & Chapman 2010; Binning et al. 2010). Fixation of this plastic trait in some populations may be achieved through mutations in cisregulatory regions of plasticity-related genes that constrain their environmental responsiveness. As many of the genes included in our study are known to be mechanically responsive, their expression is likely to be mediated by shear stress responsive elements (SSREs), cis-regulatory elements of mechanically responsive genes (Nomura & Takano-Yamamoto 2000). Alterations to the number or position of these elements might alter the degree of response to mechanical strain of these genes. Determining whether such regulatory evolution has occurred in natural populations or between closely related species of cichlids that can differ markedly in their pharyngeal jaw morphologies will be the subject of our future work.

In conclusion, we have identified numerous transcriptional changes that contribute to phenotypic plasticity in the LPJs of A. alluaudi. These genes include various mechano-responsive genes identified in the bones and teeth of mammals, which will inform future studies of the cellular and developmental basis of plasticity in the LPJs. Empirical assessment of the importance of plasticity in establishing phenotypes of wild populations, and its potential importance in generating divergent PJA morphologies in distantly related cichlid species can be achieved in the future through examining the expression of genes identified by our study in a phylogenetic context. One might speculate, and we plan to test, that parallel evolution of molariform morphologies of the PJAs of different cichlid radiations is caused by the induction of similar expression patterns, which might have become fixed through the process of genetic assimilation.

#### Acknowledgements

We dedicate this manuscript to the memory of Frans Witte, a pioneer in cichlid biology who has recently passed away. Funding was provided by a grant from the Deutsche Forschungsgemeinschaft to HG, the Zukunftskolleg at the University of Konstanz to HG, the DAAD to CF and supported by the University of Konstanz to AM. We wish to thank Patrick Niemantsverdriet and Frans Witte from the University of Leiden for generously providing their strain of *A. alluaudi* and Eckhard Witten and Ralf Schneider for useful comments on this manuscript. Madoka Krick and Maria-Louise Spreitzer are thanked for their assistance with the morphometric analysis.

A.M. and H.G. conceived and designed the experiments; H.G. and X.F. performed the split-brood experiment and qRT-PCR; P.F. performed RNA-seq; H.G., S.F., P.F. and C.F. analyzed the data. H.G. wrote the manuscript, with all authors contributing.
